

LB11873 — Monolithic Digital IC

For Polygonal Mirror Motors

Three-Phase Brushless Motor Driver

Overview

The LB11873 is a 3-phase brushless motor driver developed for driving the polygonal mirror motor used in plain-paper copiers and similar products. This IC can implement the circuits required for polygonal mirror motor drive (speed control and driver circuits) in a single chip.

The LB11873 implements low-noise/low-vibration PWM drive by changing the current at phase switching gradually to reduce motor noise.

Functions

- Three-phase bipolar drive (quiet direct PWM)
- PLL speed control circuit
- Hall sensor FG support
- Dedicated external clock
- Brake mode switching circuit (free running and reverse braking)
- Phase lock detection output (with masking function)
- Built-in current limiter, constraint protection, undervoltage protection, thermal protection, and CLK line disconnection protection circuits
- Input pins support 3V system microcontrollers

Specifications

Absolute Maximum Ratings at Ta = 25°C

Parameter	Symbol	Conditions	Ratings	Unit
Supply voltage	V _{CC} max		30	V
Output current	I _O max	T ≤ 500ms	1.8	A
Allowable power dissipation 1	Pd max1	Independent IC	0.9	W
Allowable power dissipation 2	Pd max2	When mounted on a circuit board *1	2.1	W

*1 Specified circuit board : 114.3 × 76.1 × 1.6mm³, glass epoxy.

Pin Assignment

Top view

Hall sensor input waveforms and output current waveform

(1) When the Hall sensor input amplitude is small or when the input waveform slope is low

180° drive: Current flows during all periods; there are on off periods (180° drive)

(2) When the Hall sensor input amplitude is larger or when the input waveform slope is steep

In this case, periods in which drive is off will occur (the off periods vary depending on the Hall sensor inputs).

29	V _{CC}	Power supply. Connect a capacitor (a few tens of μF or larger) between this pin and ground so that noise does not enter the IC.	
3, 30 31, 32 34, 36	NC	Since this pin is not connected internally to the chip, it can be used for wiring connections.	
	FRAME	Connect this pin to ground.	

LB11873 Overview

1. Speed control circuit

Since the LB11873 adopts PLL speed control, it provides precise, low-jitter, and stable motor operation. This PLL circuit compares the falling edge of the CLK signal with the FG signal (edges on which the IN1 input changes from low to high and FGS output rising edges) and controls motor operation based on the difference.

During control operation, the FG servo frequency is the same as the CLK signal frequency.

$$f_{FG} (\text{servo}) = f_{CLK}$$

2. Output drive circuit

This IC minimizes motor vibration and noise by changing the output current smoothly during phase switching. Since the change (slope) imposed on the output current during phase switching uses the slope of the Hall sensor input waveform, the changes in the output waveforms at phase switching will become too steep if the Hall sensor input waveform slope is steep. This will reduce the noise and vibration reducing effect of this technique. Thus care is required concerning the slope of the Hall sensor input waveform.

Low side output transistor PWM switching is used for motor speed control and the drive output is adjusted by changing the duty. The diode between OUT and VM used for the regenerative current when the PWM is off is built into this IC. Due to the parasitic diode between OUT and ground, if reverse control mode (torque braking) is selected for braking, an external Schottky barrier diode must be used. Also, if there are problems when the output current is large (for example, incorrect operation or waveform disruption during low side kickback) a Schottky barrier diode must be connected between OUT and ground.

Note that if it is necessary to reduce IC thermal dissipation during constant-speed operation, it may be effective to insert a Schottky barrier diode between OUT and VM. This effect occurs because the regenerative current during PWM switching will be dissipated in the external diode instead of the IC's internal diode.

3. Current limiter circuit

The current limiter circuit limits the drive current to a current determined by the equation $I = V_{RF}/R_f$, where $V_{RF} = 0.5V$ (typical) and R_f is the current detection resistor. The limiting operation works by reducing other output on duty to suppress the drive current.

The current limiter circuit detects the reverse recovery current due to PWM operation and, to assure that the current limiting operation is not performed incorrectly, provides a delay of about $2\mu s$ before it operates. Since the changes in the current levels at startup (the state where there is no counterelectromotive force from the motor) will be rapid if either the motor coil resistance is low or if the inductance is low, there are cases where current limiter will operate at a current level above that set due to this delay. In these cases, it will be necessary to take the amount of current increase due to the delay into account when setting the current limit value.

4. Power saving circuit

This IC goes into a power saving state in which current drain is reduced when set to the stop state. This power saving state is implemented by cutting the bias current to most of the circuits in the IC. The 5V regulator output, however, is still output when the IC is in the power saving state.

5. Reference clock

Care must be taken to assure that no noise due to chattering or other problems appears on the externally input clock signal. While the input circuit is designed with hysteresis, noise must be rejected by, for example, inserting capacitors in the clock line if noise problems occur.

The LB11873 provides a built-in clock disconnection protection circuit. At clock frequencies lower than the frequency determined by the following equation, the LB11873 will not perform its normal control operation, but rather will operate in an intermittent mode.

$$f \text{ (Hz)} \approx 1.02 \div \text{CCSD} \quad \text{CCSD } (\mu\text{F}) : \text{ the capacitor connected between the CSD pin and ground.}$$

If a 0.033 μ F capacitor is used, the frequency will be about 31Hz.

If the IC is set to the start state with absolutely no clock signal provided, the motor will first start to turn somewhat and then the drive will be turned off.

If motor rotation stops, a time in excess of the constraint protection operating time elapses, and then the clock signal is applied again, drive operation will not be restarted. However, if the clock signal is reapplied before the constraint protection circuit operates, drive operation will restart.

6. PWM frequency

The PWM frequency is determined by the capacitance of the capacitor (C) connected to the PWM pin.

$$f_{\text{PWM}} \approx 1/(43000 \times C)$$

If a 680pF capacitor is used, the circuit will oscillate at about 34kHz. If the PWM frequency is too low the motor will emit switching noise, and if it is too high the power loss in the output will increase. A frequency in the range 15kHz to 50kHz is desirable. This capacitor must be connected between this pin and the GND pin by lines that are as short as possible to make this circuit immune to noise.

The capacitor ground side must be connected as close as possible to the IC control block ground (the GND1 pin), to minimize the influence of the output.

7. Hall sensor input signals

The Hall sensor input signals must have an amplitude (differential) of over 50mVpp. If disruption of the output waveforms occurs due to noise on these signals, capacitors must be connected between the Hall sensor inputs (between the + and - sides).

8. FCS pin

The capacitor (about 0.1 μ F) connected to the FC pin is required for correction of the control loop frequency characteristics.

9. Constraint protection circuit

The LB11873 includes a built-in constraint protection circuit to protect the IC and the motor if the motor is physically constrained from turning.

If FG signal (one side edge of IN1) does not switch states for a period in excess of a certain fixed time in the start state, the PWM drive side output is turned off.

The time is set by the capacitor connected to the CSD pin.

$$\text{Set time (seconds)} \approx 30.5 \times 0.98 \times \text{CCSD } (\mu\text{F})$$

If a 0.033 μ F capacitor is used, the protection operation time will be about 0.99 seconds.

The constraint protection state can be cleared by either switching to the stop state (and remaining for over 100 μ s) or turning the power off and then on again. Note that the constraint protection circuit may not operate correctly if there is noise on the FG signal when the motor is physically constrained.

10. Phase lock signal**(1) Phase lock range**

Since this IC does not have a speed system counter, the speed error range in the phase locked state cannot be determined by the IC characteristics alone. (This is because the range is affected by the acceleration with changes in the FG frequency.) If it is necessary to stipulate this in conjunction with a motor, it will be necessary to measure the range with the actual motor state. Since speed errors occur easily in states where the FG acceleration is large, it is thought that the lock pull-in time at startup and the unlock time due to clock switching will be the cases where the speed error is the largest.

(2) Phase lock signal mask function

It is possible to assure that the lock signal is output in stable states by masking the short-term low levels due to hunting during lock pull-in. Note, however, that the lock signal output will be delayed by the amount of the mask time.

The mask time is set by the capacitor connected between the CLD pin and ground.

$$\text{Mask time (s)} \approx 6.5 \times 0.98 \times \text{CCSD} (\mu\text{F})$$

When a 0.033 μF capacitor is used, the mask time will be about 210ms. If full masking is required, the mask time must be set with an adequate margin.

11. Initial reset

To apply an initial reset to the logic circuit, the IC goes to the reset state until the CSD pin voltage changes from 0V to about 0.63V. After the reset is cleared, drive will start. The reset time can be calculated quite closely with the following equation.

$$\text{Reset time (s)} \approx 0.13 \times \text{CCSD} (\mu\text{F})$$

A reset time of over 100 μs is required.

12. Power supply stabilization

Since this IC is used in switching drive applications with large output currents, the power supply line is easily disrupted.

Therefore it is necessary to connect an adequately large capacitor between the VCC pin and ground.

The capacitor ground side is connected to the GND2 pin, which is the power system ground, and must be connected as close as possible to the pin.

If the capacitor (an electrolytic capacitor) cannot be connected close to the pin, a ceramic capacitor of about 0.1 μF must be connected close to the pin.

If reverse control mode (torque braking) is selected for braking, since there will be states where the current returns to the power supply, the power supply line level will be especially subject to disruption. Since the power supply line is most easily disrupted during lock pull-in at high speeds, designers must analyze this case carefully and select an adequately large capacitor.

Since the power supply line is particularly susceptible to disruption if a diode is inserted in the power supply line to prevent destruction of the IC by reverse connection, an even larger capacitor must be selected in this case.

13. VREG stabilization

Connect a capacitor with a value over 0.1 μF to stabilize the VREG voltage, which is the IC's control circuit power supply. This capacitor's ground side must be connected as close as possible to the IC's control block ground (the GND1 pin).

14. Error amplifier system components

The external components for the error amplifier block must be located as close as possible to the IC to minimize the influence of noise. These components must also be located as far from the motor as possible.

15. FRAME pin

An electrolytic capacitor must be connected between the FRAME pin and GND2 with the capacitor's ground side is connected to GND2.
